Abstract

The Relativistic Random Phase Approximation (RRPA) is derived from the Time-dependent Relativistic Mean Field (TD RMF) theory in the limit of small amplitude oscillations. In the *no-sea* approximation of the RMF theory, the RRPA configuration space includes not only the ususal particle-hole ph-states, but also αh-configurations, i.e. pairs formed from occupied states in the Fermi sea and empty negative-energy states in the Dirac sea. The contribution of the negative energy states to the RRPA matrices is examined in a schematic model, and the large effect of Dirac sea states on isoscalar strength distributions is illustrated for the giant monopole resonance in ^{116}Sn. It is shown that, because the matrix elements of the time-like component of the vector meson fields which couple the αh-configurations with the ph-configurations are strongly reduced with respect to the corresponding matrix elements of the isoscalar scalar meson field, the inclusion of states with unperturbed energies more than 1.2 GeV below the Fermi energy has a pronounced effect on giant resonances with excitation energies in the MeV region. The influence of nuclear magnetism, i.e. the effect of the spatial components of the vector fields is examined, and the difference between the non-relativistic and relativistic RPA predictions for the nuclear matter compression modulus is explained.

I. INTRODUCTION

Models based on the Relativistic Mean Field (RMF) approximation provide a microscopic self-consistent description of nuclear structure phenomena (for reviews, see Refs. [1–4]). In this framework classical equations of motion are derived self-consistently from a fully relativistic Lagrangian. Vacuum polarization effects, as well as Fock exchange terms, are usually not taken into account explicitly. This framework, however, is based on an effective theory and the parameters of effective interactions are determined from a set of experimental data. In adjusting the parameters of the effective Lagrangian, a large part of vacuum polarization effects and effects of exchange terms are already taken into account. In fact, both contributions have been treated explicitly in nuclear matter and in some finite spherical nuclei [5–9], and it has been shown that these contributions are not small. However, by renormalizing the parameters of the effective Lagrangian, virtually identical results for ground-state properties have been obtained without the inclusion of vacuum polarization and exchange terms. Essential for a quantitative description of properties of complex nuclei are the non-linear terms in the meson sector [10], which in a simple way include an effective density dependence of the meson coupling parameters.

The relativistic mean-field models have been mostly applied in the description of ground-state properties of nuclei all over the periodic table. In several cases this framework has also been very successfully applied to excited states. For example, the cranked relativistic mean-field model [11] describes a large variety of phenomena in rotational bands of superdeformed nuclei [12–14]. Another example is the Time-dependent RMF model which has been used to describe the dynamics of giant resonances in nuclei [15–17]. From the time evolution of multipole moments of the single-particle density, the excitation energies of giant resonances can be determined. Excellent agreement with experimental values of isoscalar and isovector giant monopole, giant quadrupole and the isovector giant dipole resonances has been obtained. The disadvantage of the time-dependent approach is that in some cases the large computational effort prevents an accurate description of excited states as, for instance, the dynamics of low-lying collective excitations.

The Relativistic Random Phase Approximation (RRPA) represents the small amplitude limit of the time-dependent relativistic mean-field theory. Some of the earliest applications of the RRPA [18–22] to finite nuclei include the description of low-lying negative parity excitations in ^{16}O [18], and studies of isoscalar giant resonances in light and medium nuclei [19]. These RRPA calculations, however, were based on the most simple, linear $\sigma - \omega$ relativistic mean field model. Only recently non-linear meson self-interaction terms have been taken included in RRPA calculations [23,24]. However, in these calculations the RRPA configuration space included only ordinary particle-hole pairs. This seems a reasonable approximation, since the states formed from occupied positive-energy states in the Fermi sea and empty negative energy states in the Dirac sea, have unperturbed energies more than 1.2 GeV below the Fermi level. It turned out, however, that excitation energies of isoscalar resonances calculated in this way were very different from those obtained in the TD RMF approach with the same effective interactions [25,26].

Since it is well known that in the non-relativistic framework the RPA corresponds to the small amplitude limit of time-dependent Hartree-Fock (TDHF) (see, e.g., Ref. [27]), these discrepancies remained an open puzzle for a couple of years. Only recently it has been shown

[28,29] that, in order to reproduce results of time-dependent relativistic mean-field calculations for giant resonances, the RRPA configuration space must contain negative-energy states from the Dirac sea. In principle, if the Dirac sea were fully occupied, these configurations would be forbidden by the Pauli principle. However, in the *no-sea* approximation the negative-energy states do not contribute to the nucleon densities, i.e. these states are not occupied. It is, thus, possible to form αh pairs (α empty state in the Dirac sea, h occupied state in the Fermi sea) and include them in the RRPA configuration space. Although formally possible, and also necessary in order to preserve symmetries, this procedure raises some serious conceptual problems because the αh configurations have negative unperturbed excitations energies. This means that the energy surface is no longer positive definite. The static solutions of the RMF equations correspond to saddle points on the energy surface, rather than to minima as in non-relativistic Hartree-Fock calculations. It is not, therefore, a priori clear that small amplitude oscillations around these stationary solutions will be stable. Furthermore, it is not obvious why configurations with unperturbed energies more than 1.2 GeV below the Fermi level have such a pronounced effect on the excitation energies of giant resonances in the MeV region. In non-relativistic calculations, for instance, it has been noted [30] that *ph*-configurations with very large excitation energies affect the position of the spurious mode, but they have no effect on the excitation energies of giant resonances.

The purpose of the present investigation is to clarify some of these problems and to understand in a better way the relation between the RRPA and the TD RMF in the *no-sea* approximation. The paper is organized as follows: the time-dependent RMF model is analyzed in Sec. II. In Sec. III the RRPA is derived from the TDRMF equations in the limit of small amplitude motion. In particular, we discuss the importance of αh-pairs in the RRPA configuration space. In Sec. IV we introduce a relativistic extension of the Brown-Bolsterli model and solve it in the linear response approximation. It is shown how large matrix elements, which couple the αh-sector with the *ph*-configurations, can arise in the RRPA matrices. The large effect of Dirac sea states on isoscalar strength distributions is illustrated in Sec. V. The results are summarized in Sec. VI.

II. THE TIME-DEPENDENT RELATIVISTIC MEAN-FIELD MODEL

In quantum hadrodynamics the nucleus is described as a system of Dirac nucleons which interact through the exchange of virtual mesons and photons. The model is based on the one-boson exchange description of the nucleon-nucleon interaction. The Lagrangian density reads [1]

$$
\begin{aligned}
\mathcal{L} = \bar{\psi}\left(i\gamma\cdot\partial - m\right)\psi \;+\; \frac{1}{2}\partial\sigma\cdot\partial\sigma - \frac{1}{2}m_\sigma\sigma^2 \\
-\;\frac{1}{4}\Omega_{\mu\nu}\Omega^{\mu\nu} + \frac{1}{2}m_\omega^2\omega^2 \;-\; \frac{1}{4}\vec{\mathrm{R}}_{\mu\nu}\vec{\mathrm{R}}^{\mu\nu} + \frac{1}{2}m_\rho^2\vec{\rho}^{\,2} \;-\; \frac{1}{4}\mathrm{F}_{\mu\nu}\mathrm{F}^{\mu\nu} \\
-\;\bar{\psi}[g_\sigma\sigma \;+\; g_\omega\gamma\cdot\omega \;+\; g_\rho\gamma\cdot\vec{\rho}\vec{\tau} \;+\; e\gamma\cdot A\frac{(1-\tau_3)}{2}]\psi\;. \qquad (1)
\end{aligned}
$$

Vectors in isospin space are denoted by arrows, and bold-faced symbols will indicate vectors in ordinary three-dimensional space; a dot denotes the scalar product in Minkowski space ($\gamma\cdot\omega = \gamma^\mu\omega_\mu = \gamma_0\omega_0 - \boldsymbol{\gamma}\boldsymbol{\omega}$). The Dirac spinor ψ denotes the nucleon with mass m. m_σ, m_ω, and m_ρ are the masses of the σ-meson, the ω-meson, and the ρ-meson, and g_σ, g_ω, and g_ρ are the corresponding coupling constants for the mesons to the nucleon, and $e^2/\hbar c = 1/137.036$. Eq.(1), $\Omega^{\mu\nu}$, $\vec{R}^{\mu\nu}$, and $F^{\mu\nu}$ denote the field tensors of the vector fields ω, ρ, and of the photon, respectively:

$$\begin{aligned}
\Omega^{\mu\nu} &= \partial^\mu\omega^\nu - \partial^\nu\omega^\mu \ , \\
\vec{R}^{\mu\nu} &= \partial^\mu\vec{\rho}^{\,\nu} - \partial^\nu\vec{\rho}^{\,\mu} \ , \\
F^{\mu\nu} &= \partial^\mu A^\nu - \partial^\nu A^\mu \ . \qquad (2)
\end{aligned}$$

If the bare masses m, m_ω, and m_ρ are used for the nucleons and the ω and ρ mesons, there are only four free model parameters: m_σ, g_σ, g_ω and g_ρ. Their values can be adjusted to experimental data of just few spherical nuclei. This simple model, however, is not flexible enough for a quantitative description of properties of complex nuclear systems. An effective density dependence has been introduced [10] by replacing the quadratic σ-potential $\frac{1}{2}m_\sigma^2\sigma^2$ with a quartic potential $U(\sigma)$

$$U(\sigma) \ = \ \frac{1}{2}m_\sigma^2\sigma^2 + \frac{1}{3}g_2\sigma^3 + \frac{1}{4}g_3\sigma^4 \ . \qquad (3)$$

The potential includes the nonlinear σ self-interaction, with two additional parameters g_2 and g_3. The corresponding Klein-Gordon equation becomes nonlinear, with a σ-dependent mass $m_\sigma^2(\sigma) = m_\sigma^2 + g_2\sigma + g_3\sigma^2$. More details on the relativistic mean-field formalism can be found in Refs. [1–4].

From the Lagrangian density the set of coupled equations of motion is derived. The Dirac equation for the nucleons

$$\begin{aligned}
i\partial_t\psi_i &= \hat{h}(t)\psi_i \\
&= \{\boldsymbol{\alpha}[-i\boldsymbol{\nabla} - \mathbf{V}(\mathbf{r},t)] + V(\mathbf{r},t) + \beta(m - S(\mathbf{r},t))\}\,\psi_i. \qquad (4)
\end{aligned}$$

If one neglects retardation effects for the meson fields, the time-dependent mean-field potentials

$$\begin{aligned}
S(\mathbf{r},t) &= -g_\sigma\sigma(\mathbf{r},t) \ , \\
V_\mu(\mathbf{r},t) &= g_\omega\omega_\mu(\mathbf{r},t) + g_\rho\vec{\tau}\vec{\rho}_\mu(\mathbf{r},t) + eA_\mu(\mathbf{r},t)\frac{(1-\tau_3)}{2} \ , \qquad (5)
\end{aligned}$$

are calculated at each step in time from the solution of the stationary Klein-Gordon equations

$$\begin{aligned}
\left[-\Delta + m_\sigma^2\right]\,\sigma(\mathbf{r},t) &= -g_\sigma\,\rho_s(\mathbf{r},t) - g_2\,\sigma^2(\mathbf{r},t) - g_3\,\sigma^3(\mathbf{r},t) \ , \\
\left[-\Delta + m_\omega^2\right]\,\omega_\mu(\mathbf{r},t) &= g_\omega\,j_\mu(\mathbf{r},t) \ , \\
\left[-\Delta + m_\rho^2\right]\,\vec{\rho}_\mu(\mathbf{r},t) &= g_\rho\,\vec{j}_\mu(\mathbf{r},t) \ , \\
-\Delta\,A_\mu(\mathbf{r},t) &= e\,j_{c\mu}(\mathbf{r},t) \ . \qquad (6)
\end{aligned}$$

This approximation is justified by the large masses in the meson propagators. Retardation effects can be neglected because of the short range of the corresponding meson exchange forces. In the mean-field approximation only the motion of the nucleons is quantized, the meson degrees of freedom are described by classical fields which are defined by the nucleon densities and currents. The single-particle spinors ψ_i $(i = 1, 2, ..., A)$ form the A-particle Slater determinant $|\Phi(t)\rangle$. The nucleons move independently in the classical meson fields, i.e. residual two-body correlations are not included, and the many-nucleon wave function is a Slater determinant at all times. The sources of the fields in the Klein-Gordon equations are the nucleon densities and currents calculated in the *no-sea* approximation

$$\begin{aligned}
\rho_s(\mathbf{r},t) &= \sum_{i=1}^{A} \bar{\psi}_i(\mathbf{r},t)\psi_i(\mathbf{r},t) \ , \\
j_\mu(\mathbf{r},t) &= \sum_{i=1}^{A} \bar{\psi}_i(\mathbf{r},t)\gamma_\mu\psi_i(\mathbf{r},t) \ , \\
\vec{j}_\mu(\mathbf{r},t) &= \sum_{i=1}^{A} \bar{\psi}_i(\mathbf{r},t)\vec{\tau}\gamma_\mu\psi_i(\mathbf{r},t) \ , \\
j_{c\mu}(\mathbf{r},t) &= \sum_{i=1}^{Z} \bar{\psi}_i(\mathbf{r},t)\gamma_\mu\psi_i(\mathbf{r},t) \ .
\end{aligned} \tag{7}$$

where the summation is over all occupied states in the Fermi sea. In the *no-sea* approximation the negative-energy states do not contribute to the densities and currents, i.e. vacuum polarization is explicitly neglected. However, as already discussed in the Introduction, this is an effective theory with the parameters of the Lagrangian determined from a set of experimental data. In adjusting the parameters of the effective Lagrangian, a large part of vacuum polarization effects is therefore already taken into account. It should be emphasized that the *no-sea* approximation is essential for practical applications of the relativistic mean-field model.

The stationary solutions of the relativistic mean-field equations describe the ground-state of a nucleus. They correspond to stationary points on the relativistic energy surface. The Dirac sea, i.e. the negative energy eigenvectors of the Dirac hamiltonian, is different for different nuclei. This means that it depends on the specific solution of the set of nonlinear RMF equations. The Dirac spinors which describe the ground-state of a finite nucleus (positive energy states) can be expanded, for instance, in terms of vacuum solutions, which form a complete set of plane wave functions in spinor space. This set is only complete, however, if in addition to the positive energy states, it also contains the states with negative energies, in this case the Dirac sea of the vacuum. Positive energy solutions of the RMF equations in a finite nucleus automatically contain vacuum components with negative energy. In the same way, solutions which describe excited states, as for instance states with different angular momenta which are solutions of the cranked RMF equations, contain negative energy components which correspond to the ground-state solution.

This is also true for the solutions of the time-dependent problem. Although for the stationary solutions the negative-energy states do not contribute to the densities in the *no-sea* approximation, their contribution is implicitly included in the time-dependent calculation. The coupled system of RMF equations describes the time-evolution of A nucleons in the effective mean-field potential. Starting from the self-consistent solution which describes the ground-state of the nucleus, initial conditions can be defined which correspond, for instance, to excitations of giant resonances in experiments with electromagnetic or hadron probes.

For example, the one-body proton and neutron densities can be initially deformed and/or given some initial velocities. The resulting mean-field dynamics can be described by the time-evolution of the collective variables. In coordinate space for example, these will be the multipole moments of the density distributions. At each time t, the Dirac spinors $\psi_i(t)$ can be expanded in terms of the complete set of solutions of the stationary Dirac equation $\psi_k^{(0)}$

$$\psi_i(\mathbf{r},t) = \sum_k c_k(t)\psi_k^{(0)}(\mathbf{r})\mathrm{e}^{-i\varepsilon_k t} + \sum_\alpha c_\alpha(t)\psi_\alpha^{(0)}(\mathbf{r})\mathrm{e}^{-i\varepsilon_\alpha t} \ , \tag{8}$$

where the index k runs over all positive energy eigen-solutions $\varepsilon_k > 0$ (hole states h in the Fermi sea, and particle states p above the Fermi sea), and the index α denotes eigen-solutions with negative energy $\varepsilon_\alpha < 0$. We follow the time evolution of A Dirac spinors which at time $t = 0$ form the Fermi sea of the stationary solution. This means that at each time we have a *local* Fermi sea of A time-dependent spinors which, of course, contain components of negative-energy solutions of the stationary Dirac equation. One could also start with the infinitely many negative energy solutions $\psi_\alpha(\mathbf{r}, t = 0)$ $(\varepsilon_\alpha < 0)$, and propagate them in time with the same hamiltonian $\hat{h}(t)$. Since the time-evolution operator is unitary [27]

$$i\partial_t \left\langle \psi_i | \psi_a \right\rangle = \left\langle \psi_i | h^\dagger - h | \psi_a \right\rangle = 0, \tag{9}$$

the states which form the *local* Dirac sea are orthogonal to the *local* Fermi sea at each time. This is the meaning of the *no-sea* approximation in the time-dependent problem. For small-amplitude oscillations around the stationary solution, the coefficients $c_\alpha(t)$ of the negative energy components in (8) are, of course, small.

We will first consider linear relativistic mean-field models ($g_2 = g_3 = 0$ in (3)). In the instantaneous approximation, i.e. neglecting the time derivatives ∂_t^2 in the Klein-Gordon equations, the solutions for the mean-fields are calculated from

$$\begin{aligned}
\sigma(\mathbf{r},t) &= g_\sigma \int D_\sigma(\mathbf{r},\mathbf{r}')\rho_s(\mathbf{r}',t)d^3r \ , \\
\omega_\mu(\mathbf{r},t) &= g_\omega \int D_\omega(\mathbf{r},\mathbf{r}')j_\mu(\mathbf{r}',t)d^3r \ , \\
\vec{\rho}_\mu(\mathbf{r},t) &= g_\rho \int D_\rho(\mathbf{r},\mathbf{r}')\vec{j}_\mu(\mathbf{r}',t)d^3r \ , \\
A_\mu(\mathbf{r},t) &= e \int D_{photon}(\mathbf{r},\mathbf{r}')j_{c\mu}(\mathbf{r}',t)d^3r \ .
\end{aligned} \tag{10}$$

The propagators have the Yukawa form

$$D_\phi(\mathbf{r},\mathbf{r}') = \pm\frac{1}{4\pi}\frac{\mathrm{e}^{-m_\phi|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|} \ , \tag{11}$$

where ϕ denotes the mesons σ, ω, ρ, and the photon. The plus (minus) sign is for vector (scalar) fields. In the non-linear case an analytic solution of the Klein-Gordon equation is, of course, no longer possible. The corresponding meson field is a non-linear functional of the density and currents.

The relativistic single-particle density matrix reads

$$\hat{\rho}(\mathbf{r},\mathbf{r}',t) = \sum_{i=1}^{A} |\psi_i(\mathbf{r},t)\rangle\langle\psi_i(\mathbf{r}',t)| \ . \tag{12}$$

If the Dirac spinor is written in terms of large and small components

$$|\psi_i(\mathbf{r},t)\rangle = \left(\begin{array}{c} f_i(\mathbf{r},t) \\ ig_i(\mathbf{r},t) \end{array} \right), \tag{13}$$

the density matrix takes the form

$$\rho(\mathbf{r},\mathbf{r}',t) = \left(\begin{array}{cc} \sum\limits_{i=1}^{A} f_i(\mathbf{r},t) f_i^\dagger(\mathbf{r}',t) & -i \sum\limits_{i=1}^{A} f_i(\mathbf{r},t) g_i^\dagger(\mathbf{r}',t) \\ i \sum\limits_{i=1}^{A} g_i(\mathbf{r},t) f_i^\dagger(\mathbf{r}',t) & \sum\limits_{i=1}^{A} g_i(\mathbf{r},t) g_i^\dagger(\mathbf{r}',t) \end{array} \right) . \tag{14}$$

Further, a relativistic two-body interaction is defined

$$\hat{V} = \int d^3r_1 d^3r_2 \hat{\psi}^\dagger(\mathbf{r}_1)\hat{\psi}^\dagger(\mathbf{r}_2) V(\mathbf{r}_1,\mathbf{r}_2) \hat{\psi}(\mathbf{r}_1)\hat{\psi}(\mathbf{r}_2) \ , \tag{15}$$

where $\hat{\psi}^\dagger$and $\hat{\psi}$ are the Dirac field creation and annihilation operators, and

$$V(\mathbf{r}_1,\mathbf{r}_2) = D_\sigma(\mathbf{r}_1,\mathbf{r}_2)\, \beta^{(1)}\beta^{(2)} + D_\omega(\mathbf{r}_1,\mathbf{r}_2) \left(1 - \boldsymbol{\alpha}^{(1)}\boldsymbol{\alpha}^{(2)}\right) \ . \tag{16}$$

In order to simplify the notation, we omit the ρ-meson and the photon, though they are, of course, included in actual applications of the relativistic mean-field model. Their contribution to the matrix elements of $V(\mathbf{r}_1,\mathbf{r}_2)$ is, however, much smaller than that of the σ and ω mesons.

By introducing an arbitrary complete spinor basis (the indices $k, l, \ldots$ denote both positive and negative energy states), the two-body interaction operator can be written in the form

$$\hat{V} = \frac{1}{2} \sum_{kk'll'} V_{klk'l'} \hat{\psi}_k^\dagger \hat{\psi}_l^\dagger \hat{\psi}_{l'} \hat{\psi}_{k'} \ . \tag{17}$$

The single-particle equation of motion corresponds to the time-dependent relativistic Hartree problem

$$i\partial_t \psi_i = \hat{h}(\hat{\rho})\psi_i \ , \tag{18}$$

with the Dirac Hamiltonian

$$\hat{h}(\hat{\rho}) = \boldsymbol{\alpha}\, \mathbf{p} + \beta(m + \Sigma(\hat{\rho})), \tag{19}$$

and the mass operator

$$\Sigma_{kl}(\hat{\rho}) = \sum_{k'l'} V_{kl'lk'} \rho_{k'l'} \ . \tag{20}$$

The corresponding equation of motion for the density operator reads

$$i\partial_t \hat{\rho} = \left[\hat{h}(\hat{\rho}), \hat{\rho}\right] \ , \tag{21}$$

in full analogy with the non-relativistic Hartree-Fock problem (see, e.g., Ref. [27]).

In expressing the TD RMF equations (4-6) in terms of a relativistic two-body interaction, we have eliminated the meson degrees of freedom by using the Yukawa form (11) of the meson propagators. This applies, of course, only to Lagrangians that do not contain non-linear meson self-interactions. The non-linear couplings are, however, essential for a realistic description of nuclear properties. Formally, also in this case the Klein-Gordon equations can be solved at each step in time, and the resulting meson fields are non-linear functionals of the densities and currents. The Dirac operator has still the form of Eq. (19), but the mass-operator $\Sigma_{kl}(\hat{\rho})$ becomes a much more complicated functional of the single-particle density.

The numerical solution of the full time-dependent problem with non-linear meson self-interactions does not present particular difficulties (see Refs. [15–17]). Much more difficult, however, is to eliminate the meson degrees of freedom and to derive a relativistic two-body interaction in the general case of large amplitude motion. This has only been done in the small amplitude limit [23]. The σ-field and the scalar density ρ_s are expanded in the neighborhood of the stationary ground-state solutions

$$\sigma(\mathbf{r},t) = \sigma^{(0)}(\mathbf{r})+\delta\sigma(\mathbf{r},t) \ , \tag{22}$$

$$\rho_s(\mathbf{r},t) = \rho_s^{(0)}(\mathbf{r})+\delta\rho_s(\mathbf{r},t) \ . \tag{23}$$

The corresponding Klein-Gordon equation (6) for the σ-field is solved by linearization, i.e. up to terms linear in $\delta\sigma$ we obtain

$$\left[-\Delta + m_\sigma^2(\mathbf{r})\right] \delta\,\sigma(\mathbf{r},t) = -g_\sigma \delta\,\rho_s(\mathbf{r},t) \ , \tag{24}$$

with

$$m_\sigma^2(\mathbf{r}) = \left.\frac{\partial^2 U}{\partial \sigma^2}\right|_{\sigma=\sigma^{(0)}(\mathbf{r})} \ . \tag{25}$$

The σ-meson propagator is defined by the equation

$$\left[-\Delta + m_\sigma^2(\mathbf{r})\right] D_\sigma(\mathbf{r},\mathbf{r}') = -\delta(\mathbf{r}-\mathbf{r}') \ , \tag{26}$$

and it has been determined numerically in the RRPA calculations of Refs. ([23–25]). In the following only the small amplitude limit will be studied, and therefore we do not need to worry about the more general problem of large amplitude motion.

III. THE SMALL AMPLITUDE LIMIT OF TD RMF AND THE RELATIVISTIC RPA

In this section we study the response of the density matrix $\hat{\rho}(t)$ to an external one-body field

$$\hat{F}(t) = \hat{F}\mathrm{e}^{-i\omega t} + h.c. \ , \tag{27}$$

which oscillates with a small amplitude. Assuming that in the single-particle space this field is represented by the operator

$$\hat{f}(t) = \sum_{kl} f_{kl}(t)\; \hat{a}_k^\dagger \hat{a}_l, \tag{28}$$

the equation of motion for the density operator is

$$i\partial_t \hat{\rho} = \left[\hat{h}(\hat{\rho}) + \hat{f}(t), \hat{\rho}\right] \;, \tag{29}$$

In the linear approximation the density matrix is expanded

$$\hat{\rho}(t) = \hat{\rho}^{(0)} + \delta\hat{\rho}(t) \;, \tag{30}$$

where $\hat{\rho}^{(0)}$ is the stationary ground-state density. From the definition of the density matrix (12), it follows that $\hat{\rho}\,(t)$ is a projector at all times, i.e. $\hat{\rho}\,(t)^2 = \hat{\rho}\,(t)$. In particular, this means that the eigenvalues of $\hat{\rho}^{(0)}$ are 0 and 1. In the non-relativistic case particle states above the Fermi level correspond to the eigenvalue 0, and hole states in the Fermi sea correspond to the eigenvalue 1. In the relativistic case, one also has to take into account states from the Dirac sea. In the *no-sea* approximation these states are not occupied, i.e. they correspond to the eigenvalue 0 of the density matrix. We will work in the basis which diagonalizes $\hat{\rho}^{(0)}$

$$\rho_{kl}^{(0)} = \delta_{kl}\rho_k^{(0)} = \begin{cases} 0 & \text{for unoccupied states above the Fermi level (index } p) \\ 1 & \text{for occupied states in the Fermi sea (index } h) \\ 0 & \text{for unoccupied states in the Dirac sea (index } \alpha) \end{cases} \tag{31}$$

Since $\hat{\rho}(t)$ is a projector at all times, in linear order

$$\hat{\rho}^{(0)}\delta\hat{\rho} + \delta\hat{\rho}\hat{\rho}^{(0)} = \delta\hat{\rho} \;. \tag{32}$$

This means that the non-vanishing matrix elements of $\delta\hat{\rho}$ are: $\delta\rho_{ph}$, $\delta\rho_{hp}$, $\delta\rho_{\alpha h}$, and $\delta\rho_{h\alpha}$. These are determined by the solution of the TD RMF equation (29). In the linear approximation the equation of motion reduces to

$$i\partial_t\delta\hat{\rho} = \left[\hat{h}^{(0)}, \delta\hat{\rho}\right] + \left[\frac{\partial\hat{h}}{\partial\rho}\delta\rho, \hat{\rho}^{(0)}\right] + \left[\hat{f}, \hat{\rho}^{(0)}\right] \;, \tag{33}$$

where

$$\frac{\partial\hat{h}}{\partial\rho}\delta\rho = \sum_{ph} \frac{\partial\hat{h}}{\partial\rho_{ph}}\delta\rho_{ph} + \frac{\partial\hat{h}}{\partial\rho_{hp}}\delta\rho_{hp} + \sum_{\alpha h} \frac{\partial\hat{h}}{\partial\rho_{\alpha h}}\delta\rho_{\alpha h} + \frac{\partial\hat{h}}{\partial\rho_{h\alpha}}\delta\rho_{h\alpha} \;. \tag{34}$$

In the small amplitude limit $\delta\rho$ will, of course, also display a harmonic time dependence $\mathrm{e}^{-i\omega t}$. Taking into account the fact that $\hat{h}_{kl}^{(0)} = \delta_{kl}\epsilon_k$ is diagonal in the stationary basis, we obtain

$$\begin{aligned}
(\omega - \epsilon_p + \epsilon_h)\delta\rho_{ph} &= f_{ph} + \sum_{p'h'} V_{ph'hp'}\delta\rho_{p'h'} + V_{pp'hh'}\delta\rho_{h'p'} + \sum_{\alpha'h'} V_{ph'h\alpha'}\delta\rho_{\alpha'h'} + V_{p\alpha'hh'}\delta\rho_{h'\alpha'} \\
(\omega - \epsilon_\alpha + \epsilon_h)\delta\rho_{\alpha h} &= f_{\alpha h} + \sum_{p'h'} V_{\alpha h'hp'}\delta\rho_{p'h'} + V_{\alpha p'hh'}\delta\rho_{h'p'} + \sum_{\alpha'h'} V_{\alpha h'h\alpha'}\delta\rho_{\alpha'h'} + V_{\alpha\alpha'hh'}\delta\rho_{h'\alpha'} \\
(\omega - \epsilon_h + \epsilon_p)\delta\rho_{hp} &= f_{hp} + \sum_{p'h'} V_{hh'pp'}\delta\rho_{p'h'} + V_{hp'ph'}\delta\rho_{h'p'} + \sum_{\alpha'h'} V_{hh'p\alpha'}\delta\rho_{\alpha'h'} + V_{h\alpha'ph'}\delta\rho_{h'\alpha'} \\
(\omega - \epsilon_h + \epsilon_\alpha)\delta\rho_{h\alpha} &= f_{h\alpha} + \sum_{p'h'} V_{hh'\alpha p'}\delta\rho_{p'h'} + V_{hp'\alpha h'}\delta\rho_{h'p'} + \sum_{\alpha'h'} V_{hh'\alpha\alpha'}\delta\rho_{\alpha'h'} + V_{h\alpha'\alpha h'}\delta\rho_{h'\alpha'}
\end{aligned} \tag{35}$$

or, in matrix form

$$\left[\omega\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}-\begin{pmatrix}A & B\\ B^{*} & A^{*}\end{pmatrix}\right]\begin{pmatrix}X\\ Y\end{pmatrix}=\begin{pmatrix}F\\ \bar{F}\end{pmatrix}\ , \tag{36}$$

The RRPA matrices A and B read

$$A=\begin{pmatrix}(\epsilon_p-\epsilon_h)\delta_{pp'}\delta_{hh'} & \\ & (\epsilon_\alpha-\epsilon_h)\delta_{\alpha\alpha'}\delta_{hh'}\end{pmatrix}+\begin{pmatrix}V_{ph'hp'} & V_{ph'h\alpha'}\\ V_{\alpha h'hp'} & V_{\alpha h'h\alpha'}\end{pmatrix} \tag{37}$$

$$B=\begin{pmatrix}V_{pp'hh'} & V_{p\alpha'hh'}\\ V_{\alpha p'hh'} & V_{\alpha\alpha'hh'}\end{pmatrix} \tag{38}$$

and the amplitudes X and Y are defined

$$X=\begin{pmatrix}\delta\rho_{ph}\\ \delta\rho_{\alpha h}\end{pmatrix},\quad Y=\begin{pmatrix}\delta\rho_{hp}\\ \delta\rho_{h\alpha}\end{pmatrix}\ . \tag{39}$$

The vectors which represent the external field contain the matrix elements

$$F=\begin{pmatrix}f_{ph}\\ f_{\alpha h}\end{pmatrix},\quad \bar{F}=\begin{pmatrix}f_{hp}\\ f_{h\alpha}\end{pmatrix}\ . \tag{40}$$

In conventional linear response theory (see, e.g., Ref. [27]) the polarization function $\Pi_{pqp'q'}(\omega)$ is defined by the response of the density matrix to an external field with a harmonic time dependence

$$\delta\rho_{pq}=\sum_{p'q'}\Pi_{pqp'q'}(\omega)\,f_{p'q'}\ . \tag{41}$$

Its spectral representation reads

$$\Pi_{pqp'q'}(\omega)=\sum_{\mu}\frac{\langle 0|\psi_q^{\dagger}\psi_p|\mu\rangle\langle\mu|\psi_{p'}^{\dagger}\psi_{q'}|0\rangle}{\omega-E_\mu+E_0+i\eta}-\frac{\langle 0|\psi_{p'}^{\dagger}\psi_{q'}|\mu\rangle\langle\mu|\psi_q^{\dagger}\psi_p|0\rangle}{\omega+E_\mu-E_0+i\eta}\ , \tag{42}$$

where the index μ runs over all excited states $|\mu\rangle$ with energy E_μ. In the RPA approximation the polarization function is obtained by inverting the matrix

$$\Pi(\omega)=\left[\begin{pmatrix}\omega+i\eta & 0\\ 0 & -\omega-i\eta\end{pmatrix}-\begin{pmatrix}A & B\\ B^{*} & A^{*}\end{pmatrix}\right]^{-1}\ . \tag{43}$$

$\Pi(\omega)$ is the solution of the linearized Bethe-Salpeter equation

$$\Pi(\omega)=\Pi^0(\omega)+\Pi^0(\omega)V\,\Pi(\omega)\ , \tag{44}$$

where the free polarization function is given by

$$\Pi^0_{klk'l'}(\omega)=\frac{\rho_l^{(0)}-\rho_k^{(0)}}{\omega-\epsilon_k+\epsilon_l+i\eta}\delta_{kk'}\delta_{ll'}\ . \tag{45}$$

The eigenmodes of the system are determined by the RPA equation

$$\begin{pmatrix} A & B \\ -B^* & -A^* \end{pmatrix} \begin{pmatrix} X \\ Y \end{pmatrix}_\mu = \begin{pmatrix} X \\ Y \end{pmatrix}_\mu \Omega_\mu \ . \tag{46}$$

In principle, this is a non-Hermitian eigenvalue problem. In the non relativistic case, however, it can be reduced to a Hermitian problem of half dimension, if the RPA matrices are real and if $(A+B)$ is positive definite. In this case one can also show that the eigenvalues Ω_μ^2 are positive, i.e., the RPA eigenfrequencies Ω_μ are real (see [27]).

The relativistic case is much more complicated. From Eq. (37) we notice that the matrix $(A+B)$ is not positive definite. The αh configurations have large negative diagonal matrix elements $\epsilon_{\alpha h} = \epsilon_\alpha - \epsilon_h \leq -1.2$ GeV, and the RRPA equation can no longer be reduced to a Hermitian problem of half dimension. In this case it is also not clear whether the eigenfrequencies are necessarily real, because the stability matrix

$$\mathcal{S} = \begin{pmatrix} A & B \\ B^* & A^* \end{pmatrix} \tag{47}$$

is no longer positive definite. Rather than minima, the solutions of the RMF equations are saddle points [32] in the multi-dimensional energy surface, and the Thouless theorem [33], which states that a positive definite stability matrix $\mathcal{S}$ leads to a stable RPA equation with real frequencies, does not apply.

However, the opposite is not true: if the stability matrix is not positive definite, it does not automatically follow that the eigenvalues of the corresponding RPA matrix are not real. In fact, cases like this occur also in the non relativistic RPA in the neighborhood of phase transitions, where the interaction V is very large and attractive. The positive energies $\varepsilon_p - \varepsilon_h$ on the diagonal of the stability matrix are not large enough, as compared to the matrix elements of V, to guarantee positive eigenvalues of $\mathcal{S}$. In the relativistic case the energies on the diagonal $\varepsilon_\alpha - \varepsilon_h$ are negative. Even for small matrix elements of V the stability matrix $\mathcal{S}$ will have negative eigenvalues. However, as long as the diagonal part dominates, i.e. as long as we are not in a neighborhood of a phase transition, the RRPA eigenfrequencies are real. This can be easily demonstrated if instead of the RPA amplitudes X and Y, we define the generalized coordinates Q and momenta P

$$Q = \frac{1}{\sqrt{2}}(X - Y^*), \qquad P = \frac{i}{\sqrt{2}}(X + Y^*) \ . \tag{48}$$

In the small amplitude limit the time-dependent mean field equations take the form of classical Hamiltonian equations (for details see Ref. [27], Chapt. 12) for the Hamiltonian function

$$\mathcal{H}(P,Q) = \frac{1}{2} \begin{pmatrix} P^* & -P \end{pmatrix} \mathcal{M}^{-1} \begin{pmatrix} P \\ -P^* \end{pmatrix} + \frac{1}{2} \begin{pmatrix} Q^* & Q \end{pmatrix} \mathcal{S} \begin{pmatrix} Q \\ Q^* \end{pmatrix}, \tag{49}$$

with the inertia tensor

$$\mathcal{M} = \begin{pmatrix} A & -B \\ -B^* & A^* \end{pmatrix}^{-1} \ . \tag{50}$$

The large negative diagonal matrix elements are also present in the inertia tensor. If the off-diagonal matrix elements are not too large, a negative inertia and a negative curvature will again result in real frequencies. In all applications of RRPA we have found real frequencies, though in none of these cases the stability matrix $\mathcal{S}$ was positive definite. This also explain why the time-dependent RMF equations have stable solutions which describe oscillations with real frequencies around the static solution, although the static solution itself corresponds to a saddle point.

The solution of the RPA equations in configuration space is much more complicated in the relativistic case. Firstly, because in addition to the usual *ph*-states, the configuration space includes a large number of αh-states. A further complication arises because the full non-Hermitian RPA matrix has to be diagonalized, even in cases when the matrix elements are real. The usual method [27], which reduces the dimension of the RPA equations by half does not apply.

Summarizing the results of this section, we have shown that the relativistic RPA represents the small amplitude limit of the time-dependent RMF theory. However, because the RMF theory is based on the *no-sea* approximation, the RRPA configuration space includes not only the ususal *ph*-states, but also αh-configurations, i.e. pairs formed from occupied states in the Fermi sea and empty negative-energy states in the Dirac sea. At each time $t \neq 0$ the occupied positive energy states can have non-vanishing overlap with both positive and negative energy solutions calculated at $t = 0$. If the density matrix $\hat{\rho}(t)$ is represented in the basis which diagonalizes the static solution $\hat{\rho}^{(0)}$, it contains not only the usual components $\delta\hat{\rho}_{ph}$ with a particle above the Fermi level and a hole in the Fermi sea, but also components $\delta\hat{\rho}_{\alpha h}$ with a particle in the Dirac sea and a hole in the Fermi sea.

One of the important advantages of using the time-dependent variational approach is that it conserves symmetries. It is well known from non-relativistic time-dependent mean field theory that symmetries are connected with zero energy solutions of the RPA, i.e. the Goldstone modes, and it is one of the advantages of RPA that it restores the symmetries broken by the mean field. This has already been realized in the early studies of symmetry conservation in RRPA, and it has been emphasized by Dawson and Furnstahl in Ref. [21], that it is essential to include the αh configuration space in order to bring the Goldstone modes to zero energy.

However, it was not anticipated that negative energy states in the RRPA configuration space could have dramatic effects on the excitation energies of giant resonances, as we will show in the following sections. It is not obvious that basis states with unperturbed energies more than 1.2 GeV below the Fermi energy, can have a big influence on giant resonances with excitation energies in the MeV region. In the following section we will study a simple model which provides a deeper insight into this problem.

IV. A SEPARABLE MODEL

The model studied in this section represents a relativistic extension of the Brown and Bolsterli model [31], which has played an essential role in the understanding of the microscopic picture of collective excitations.

The single-particle basis consists of 4 states, each of them Ω-fold degenerate ($\nu = 1, \ldots \Omega$). The first two states (1 and 2) correspond to particle levels with the free mass m, the states 3 and 4 correspond to the negative energy levels with free mass $-m$. The model Hamiltonian reads

$$H = H_0 - \lambda_s S^\dagger S + \lambda_v V^\dagger V \ , \tag{51}$$

where H_0 is the Hamiltonian which describes free Dirac particles

$$H_0 = \sum_{i=1}^{A} \left(\alpha \mathbf{p_i} + \beta \mathbf{m_i} + \frac{\mathbf{1}}{\mathbf{2}} \sigma \varepsilon_\mathbf{i} \right) \ , \tag{52}$$

with

$$\alpha = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \quad \sigma = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \tag{53}$$

In Eq.(52) $m_i = m$ is the free mass of particle i, $p_i = p$ denotes its momentum, and $\varepsilon_i = \varepsilon_0 \ll m$ induces a small splitting between the levels 1 and 2 (and, of course, between 3 and 4).

The interaction consists of an attractive scalar field S and a repulsive vector field V

$$S = \sum_{i=1}^{A} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \end{pmatrix}_i , \qquad V = \sum_{i=1}^{A} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}_i , \tag{54}$$

with the strength parameters λ_s and λ_v. In the formalism of second quantization the operators $H_{0,}$ S and V take the forms

$$\begin{aligned} H_0 = {} & p \sum_\nu c_{1\nu}^\dagger c_{3\nu} + c_{2\nu}^\dagger c_{4\nu} + h.c. \\ & + m \sum_\nu c_{1\nu}^\dagger c_{1\nu} + c_{2\nu}^\dagger c_{2\nu} - c_{3\nu}^\dagger c_{3\nu} - c_{4\nu}^\dagger c_{4\nu} \\ & + \frac{\varepsilon_0}{2} \sum_\nu c_{1\nu}^\dagger c_{1\nu} - c_{2\nu}^\dagger c_{2\nu} + c_{3\nu}^\dagger c_{3\nu} - c_{4\nu}^\dagger c_{4\nu} \ , \end{aligned} \tag{55}$$

$$S = \sum_\nu c_{1\nu}^\dagger c_{2\nu} - c_{3\nu}^\dagger c_{4\nu} + h.c. \ , \tag{56}$$

$$V = \sum_\nu c_{1\nu}^\dagger c_{2\nu} + c_{3\nu}^\dagger c_{4\nu} + h.c. \tag{57}$$

At the mean field level the diagonalization of the Dirac operator

$$H_0 = \begin{pmatrix} m + \frac{\varepsilon_0}{2} & 0 & p & 0 \\ 0 & m - \frac{\varepsilon_0}{2} & 0 & p \\ p & 0 & -m + \frac{\varepsilon_0}{2} & 0 \\ 0 & p & 0 & -m - \frac{\varepsilon_0}{2} \end{pmatrix} , \tag{58}$$

result in the eigenvalues

$$\epsilon_p = E + \frac{\varepsilon_0}{2}, \qquad \epsilon_h = E - \frac{\varepsilon_0}{2}, \qquad \epsilon_\alpha = -E + \frac{\varepsilon_0}{2}, \qquad \epsilon_{\alpha'} = -E - \frac{\varepsilon_0}{2}, \tag{59}$$

and the corresponding eigenvectors are

$$\psi_p = \begin{pmatrix} f \\ 0 \\ g \\ 0 \end{pmatrix} , \quad \psi_h = \begin{pmatrix} 0 \\ f \\ 0 \\ g \end{pmatrix} , \quad \psi_\alpha = \begin{pmatrix} -g \\ 0 \\ f \\ 0 \end{pmatrix} , \quad \psi_{\alpha'} = \begin{pmatrix} 0 \\ -g \\ 0 \\ f \end{pmatrix} , \tag{60}$$

respectively. We use the notation

$$E = \sqrt{p^2 + m^2},, \qquad f = \cos\frac{\phi}{2}, \qquad g = \sin\frac{\phi}{2} , \tag{61}$$

with

$$\tan\frac{\phi}{2} = \frac{p}{m+E} . \tag{62}$$

A realistic choice of single particle energies is

$$\begin{aligned} \epsilon_{ph} &= \epsilon_p - \epsilon_h = \varepsilon_0 \approx 10 \text{ MeV} , \\ \epsilon_{\alpha h} &= \epsilon_\alpha - \epsilon_h = -2E + \varepsilon_0 \simeq -2 \text{ GeV} , \\ \epsilon_{\alpha' h} &= \epsilon_{\alpha'} - \epsilon_h = -2E \simeq -2 \text{ GeV} . \end{aligned} \tag{63}$$

In realistic calculations the ratio between large and small components of the Dirac spinors is approximately $f/g \approx 30$, i.e., $\phi \simeq 33^0$. In the basis (60) the matrices of the operators S and V are

$$S = \sum_i \begin{pmatrix} 0 & \cos\phi & 0 & -\sin\phi \\ \cos\phi & 0 & -\sin\phi & 0 \\ 0 & -\sin\phi & 0 & -\cos\phi \\ -\sin\phi & 0 & -\cos\phi & 0 \end{pmatrix}_i , \tag{64}$$

$$V = \sum_i \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}_i . \tag{65}$$

We notice the essential matrix elements

$$\begin{array}{ll} S_{ph} = \cos\phi & V_{ph} = 1 \\ S_{\alpha h} = -\sin\phi & V_{\alpha h} = 0 \\ S_{\alpha' h} = 0 & V_{\alpha' h} = 0 . \end{array} \tag{66}$$

In analogy to the Brown-Bolsterli model, the unperturbed polarization function is

$$\Pi^0_{FF'}(\omega) = \frac{2\varepsilon_0 \Omega F_{ph} F'_{ph}}{\omega^2 - \varepsilon_0^2 + i\eta} + \frac{2\varepsilon_{\alpha h} \Omega F_{\alpha h} F'_{\alpha h}}{\omega^2 - \varepsilon_{\alpha h}^2 + i\eta} , \tag{67}$$

where the operators $F,\ F' \in \{S,\ V\}$. In particular,

$$\Pi^0_{SS}(\omega) = \frac{2\varepsilon_0\Omega\cos^2\phi}{\omega^2 - \varepsilon_0^2 + i\eta} - \frac{2E\Omega\sin^2\phi}{\omega^2 - E^2 + i\eta} \ , \tag{68}$$

$$\Pi^0_{VV}(\omega) = \frac{2\varepsilon_0\Omega}{\omega^2 - \varepsilon_0^2 + i\eta} \ , \tag{69}$$

$$\Pi^0_{VS}(\omega) = \Pi^0_{VS}(\omega) = \frac{2\varepsilon_0\Omega\cos\phi}{\omega^2 - \varepsilon_0^2 + i\eta} \ . \tag{70}$$

The RRPA frequencies are the roots of the determinant

$$\det\begin{pmatrix} 1 - & \begin{matrix} -\Pi^0_{SS}(\omega)\lambda_s & \Pi^0_{SV}(\omega)\lambda_v \\ -\Pi^0_{SV}(\omega)\lambda_s & \Pi^0_{VV}(\omega)\lambda_v \end{matrix} \end{pmatrix} = 0 \tag{71}$$

The essential difference with respect to the non-relativistic Brown-Bolsterli model is the additional term $2E\Omega\sin^2\phi/(\omega^2 - E^2 + i\eta)$ in the scalar polarization $\Pi^0_{SS}(\omega)$. Without this term (i.e. $\phi = 0$), the eigenfrequencies would be determined by

$$\omega^2 = \varepsilon_0^2 - 2\varepsilon_0\Omega(\lambda_s - \lambda_v) \ , \tag{72}$$

with the usual cancellation of scalar and vector interactions. With the additional term, states with unperturbed energies at $\simeq -2E$ are included in the RPA configuration space. The interaction between these states and the *ph*-states is determined by the matrix elements of the scalar interaction

$$v_{\alpha h' hp} = -\lambda_s \cos\phi\sin\phi \ . \tag{73}$$

These matrix elements are not reduced by a similar term coming from the vector interaction. In our simplified model this vector-induced term vanishes as a consequence of the relativistic structure of the equations: while for a state from the Fermi sea the large component is the upper component of the spinor, a state from the Dirac sea has a large lower component of the spinor. Due to the γ-matrix structure of the vertex, the matrix elements of the vector interaction vanish. In realistic calculations these matrix elements do not vanish identically, but they are reduced by an order of magnitude as compared to the corresponding scalar terms.

At excitation energies in the MeV region, $\omega \ll E$ in the denominator of the second term of Eq.(68), and we obtain an energy-independent term $(2\Omega\lambda_s\sin^2\phi)/E$ in the dispersion relation. The eigenfrequencies are now determined by

$$\omega^2 = \varepsilon_0^2 - \varepsilon_0 2\Omega(\lambda_s - \lambda_v) + \varepsilon_0 2\Omega\lambda_s\sin^2\phi\frac{E + 2\Omega\lambda_v}{E + 2\Omega\lambda_s\sin^2\phi} \ , \tag{74}$$

i.e. we find an additional repulsion for the collective state.

V. AN ILLUSTRATIVE CASE: THE GIANT MONOPOLE RESONANCE

The RPA equations can be solved either by diagonalizing the RPA matrix in configuration space (see Eq.(46)), or the response function can be calculated by solving the Bethe-Salpeter equation (44) in momentum space [19,23]. In both cases, of course, one first has to determine the single-nucleon spinors and the mean-fields which correspond to the stationary solution for the ground-state. The Dirac-Hartree equations and the equations for the meson fields are solved self-consistently in the mean-field approximation. The eigenvalue problem is solved, for instance, by diagonalization in a spherically symmetric harmonic oscillator basis [34]. From the spectrum of single-nucleon states the RPA configuration space is built: particle-hole (ph) and antiparticle-hole (αh) pairs which obey the selection rules for angular momentum, parity and isospin. The number of basis states is also determined by two cut-off parameters: the maximal ph-energy ($\epsilon_m - \epsilon_i < E_{\max}$) and the minimal αh-energy ($\epsilon_\alpha - \epsilon_i > E_{\min}$). With this basis the RPA matrix is calculated for the same effective interaction that determines the ground-state, or the free polarization function $\Pi^{(0)}$ is calculated in the response function method. Both methods require that the single-particle continuum is discretized. In order to smooth out the RPA strength function, the discrete strength distribution is folded by a Lorentzian of width Γ. In the response function method the folding is automatic if a finite value parameter $i\Gamma$ is used in the denominators of Eqs.(42-45), instead of the infinitesimal parameter $i\eta$. We have verified that identical results are obtained with both methods.

The large effect of Dirac sea states on isoscalar strength distributions is illustrated in Fig. 1, where we display the isoscalar monopole RRPA strength in ^{116}Sn calculated with the NL3 effective interaction [36] and the width of the Lorentzian is $\Gamma = 2$ MeV. Recent experimental data are available for the isoscalar giant monopole resonance in ^{116}Sn [35]. The solid curve represents the full RRPA strength and it displays a pronounced peak at 16 MeV, in excellent agreement with the measured value of 15.9 MeV [35]. Giant monopole resonances in spherical nuclei are in best agreement with experimental data, when calculated with effective Lagrangians with a nuclear matter compression modulus in the range 250-270 MeV [17,28,29]. The nuclear matter incompressibility of the NL3 effective interaction is 272 MeV.

The long-dashed curve in Fig. 1 corresponds to the to the case with no αh pairs in the RRPA configuration space. We notice that, without the contribution from Dirac sea states, the strength distribution is shifted to lower energy. The position of the peak is shifted from ≈ 16 MeV to below 10 MeV if αh pairs are not included in the RRPA basis. Quantitatively similar results are also obtained with other effective interactions. In Fig. 1 we have also separated the contributions of vector and scalar mesons to the αh matrix elements. The dash-dot-dot (dash-dot) curve corresponds to calculations in which only vector mesons (scalar mesons) were included in the coupling between the Fermi sea and Dirac sea states. Both interactions were included in the positive energy particle-hole matrix elements. The resulting strength distributions nicely illustrate the dominant contribution of the isoscalar scalar sigma meson to the αh matrix elements, in complete agreement with the result obtained in the previous section for the schematic Brown-Bolsterli model.

It is also interesting to examine the effect of the coupling via the spatial components of the vector meson fields, i.e. the term $-\boldsymbol{\alpha}^{(1)}\boldsymbol{\alpha}^{(2)}$ in the interaction of Eq. (16). In time-dependent calculations this coupling results from the nucleon currents. In Fig.2 we display the isoscalar monopole RRPA strength in ^{116}Sn calculated as follows: a) full RRPA (solid curve); b) without the matrix elements of the spatial components of the vector meson fields (dot-dashed curve); c) without the contribution of the Dirac sea to the matrix elements of the spatial components of the vector meson fields (dashed curve); and d) the free Hartree response function. The currents do not contribute to the static polarizability and to the M_{-1} moment. At finite frequencies, however, their contribution is attractive and it lowers the ISGMR energy by ≈ 2 MeV.. Therefore, if the contribution of the spatial components of the vector fields is neglected, a better agreement with experimental values would be obtained with a lower nuclear matter incompressibility: $K_\infty \simeq 230$ MeV. Incidentally, this lower value for the nuclear matter incompressibility is the one advocated by non-relativistic RPA calculations [37,38]. It has already been noted in time-dependent RMF calculations [17], as well as in recent relativistic RPA studies [29], that effective interactions which reproduce the IS GMR excitation energies in finite nuclei have a somewhat higher nuclear matter incompressibility than the corresponding non-relativistic Skyrme or Gogny interactions. Here we point to a possible solution to this puzzle: the current terms in the matrix elements of the particle-hole interaction (37,38) are given by

$$\langle p||j_1(kr)[\boldsymbol{\alpha}Y_1(\hat{\mathbf{r}})]_{J=0}||h\rangle = \langle p||j_1(kr)\begin{pmatrix} 0 & [\boldsymbol{\sigma}Y_1]_{J=0} \\ [\boldsymbol{\sigma}Y_1]_{J=0} & \end{pmatrix}||h\rangle \ , \tag{75}$$

which is a typical relativistic term because it couples large and small components of a Dirac spinor. Since they change parity, terms of the type $[\sigma Y_1]_{J=0}$ cannot contribute to the giant monopole resonance in a non-relativistic calculation.

VI. CONCLUSIONS

In the last couple of years, several discrepancies have been reported between the results obtained with the Relativistic Random Phase approximation and the Time-Dependent Relativistic Mean Field theory, when applied to the the description of small amplitude collective motion in atomic nuclei.

In order to resolve this puzzle, in the present work we have derived the RRPA from the TDRMF equations in the limit of small amplitude motion. The relativistic single particle density matrix $\hat{\rho}(t)$ has been expanded in terms of the stationary solutions of the ground-state. We have shown that the *no-sea* approximation, which is essential for practical application of the RMF theory in finite nuclei, leads to a fundamental difference between the relativistic and non-relativistic approaches. While in the non-relativistic case the time-dependent variation of the density $\delta\hat{\rho}(t) = \hat{\rho}(t) - \hat{\rho}^{(0)}$ has only *ph*-matrix elements (particle (p) above the Fermi surface, hole (h) in the Fermi sea), in the relativistic case $\delta\hat{\rho}$ contains also αh-matrix elements, where α denotes unoccupied states in the Dirac sea. The fact that states in the Dirac sea can be occupied is a direct consequence of the *no-sea* approximation. In constructing the matrix $\delta\hat{\rho}$ one has to take into account that a complete basis of single particle states contains both positive and negative energy solutions of the Dirac equation. Already in Ref. [21] it has been shown that an RRPA calculation, consistent with the mean-field model in the $no - sea$ approximation, necessitates configuration spaces that include both particle-hole pairs and pairs formed from occupied states and negative-energy states. The contributions from configurations built from occupied positive-energy states and negative-energy states are essential for current conservation and the decoupling of the spurious state.

What is less obvious, however, is that the inclusion of negative-energy single particle states in the RRPA configuration space has such a dramatic effect on the calculated excitation energies of isoscalar giant resonances. In a schematic model we have shown that, due to the relativistic structure of the RPA equations, the matrix elements of the time-like component of the vector meson fields which couple the αh-configurations with the *ph*-configurations vanish. In realistic calculations these matrix elements do not vanish identically, but they are strongly reduced with respect to the corresponding matrix elements of the isoscalar scalar meson field. As a result, the well known cancellation between the contributions of the σ and ω fields, which, for instance, leads to ground-state solution, does not take place and we find large matrix elements coupling the αh-sector with the *ph*-configurations. In addition, the number of αh-configurations which can couple to the *ph*-configurations in the neighborhood of the Fermi surface is much larger than the number of *ph*-configurations. This can increase the effect by enhancing the collectivity of the αh-configuration space.

The large effect of Dirac sea states on isoscalar strength distributions has been illustrated for the giant monopole resonance in ^{116}Sn. We have also shown that currents cannot be neglected in the calculation of giant resonances. Of course they do not occur in the static case, i.e. in the calculations of the static polarizability or the M_{-1} moment. At finite frequencies, however, time reversal invariance is broken and spatial components of the vector meson fields play an important role. This effect is known as *nuclear magnetism*. It is a genuine relativistic effect, because the matrix elements couple the large and small components of a Dirac spinor. Since the spatial components of the vector fields have the form $-\boldsymbol{\alpha}^{(1)}\boldsymbol{\alpha}^{(2)}\, D_\omega(\mathbf{r}_1, \mathbf{r}_2)$, they result in an attractive contribution which lowers the value of the calculated excitation energies of giant resonances. This explains the difference between the non-relativistic and relativistic RPA results for the isoscalar giant monopole resonances in spherical nuclei, and the corresponding predictions for the nuclear matter compression modulus.

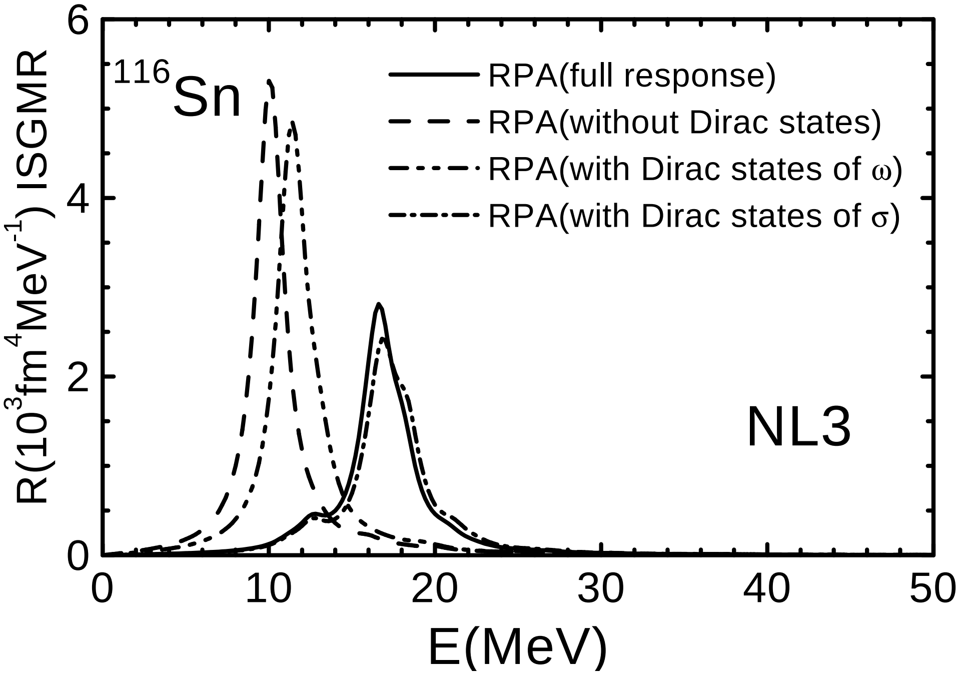

FIG. 1. ISGMR strength distributions in ^{116}Sn calculated with the NL3 effective interaction. The solid and long-dashed curves are the RRPA strengths with and without the inclusion of Dirac sea states, respectively. The dash-dot-dot (dash-dot) curve corresponds to calculations in which only vector mesons (scalar mesons) are included in the coupling between the Fermi sea and Dirac sea states.

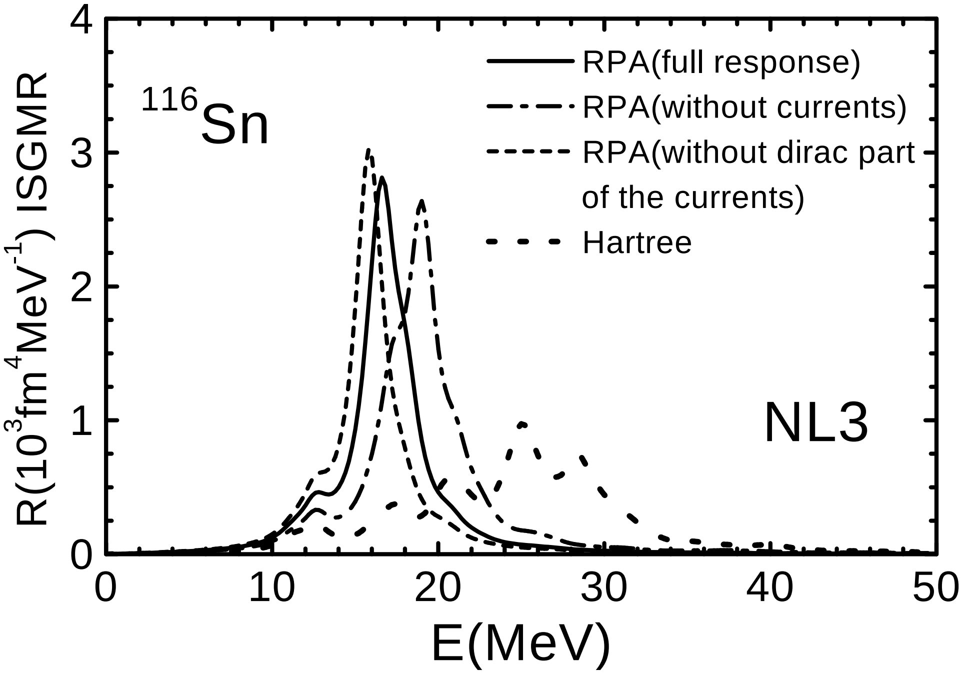

FIG. 2. Effects of nuclear magnetism on the IS GMR strength distribution in ^{116}Sn. Solid curve: full RRPA calculation; dash-dotted curve: without the matrix elements of the spatial components of the vector meson fields; dashed curve: without the contribution of the Dirac sea to the matrix elements of the spatial components of the vector meson fields. The free Hartree response is also displayed.
